EXPT NO: 5 ALGORITHM FOR TEST POWER REDUCTION

Evaluation Table			Faculty Signature
Code:	Output:	Record:	

1. AIM:

To implement Bus-Invert Coding (BIC) as a Design-for-Testability (DFT) technique for reducing dynamic power consumption during scan-based testing of VLSI circuits, and to verify its effectiveness by measuring the reduction in switching activity on the scan chain of the ISCAS-89 s27 benchmark circuit before and after encoding, using SystemVerilog simulation.

2. OBJECTIVES

- To understand the mechanism of Bus-Invert Coding and its relevance to scan test power reduction.
- To implement the ISCAS-89 s27 benchmark circuit with scan chain insertion in SystemVerilog.
- To implement a Bus-Invert Encoder that encodes scan vectors before they are shifted into the scan chain.
- To verify correct encoding behaviour through simulation and waveform analysis in EPWave.
- To quantify the reduction in switching activity achieved by BIC using transition counters.
- To analyse the effect of scan chain width on BIC power reduction efficiency using Python simulation.

3. TOOLS USED:

EDA Playground (Icarus Verilog 12.0), Google Colab (Python)

4. THEORY:

4.1 Test Power and Scan-Based Testing

Dynamic power consumption in CMOS circuits is given by:

$$P = \alpha \cdot C \cdot V^2 \cdot f$$

where α is the switching activity factor. During normal functional operation, α is typically 0.1–0.15 per bit. During scan shift operations however, flip-flops toggle with nearly random data, pushing α close to 0.5 — far exceeding functional switching levels. This excessive toggling causes IR drop, electromigration stress, and can trigger timing violations during the capture phase. Controlling switching activity during scan shift is therefore a key concern in modern DFT.

4.2 Bus-Invert Coding

Bus-Invert Coding was originally proposed for on-chip data buses and is adapted here for the scan chain. The principle is based on the Hamming distance between consecutive scan vectors. When the number of bit transitions between the current vector and the previously loaded vector exceeds half the bus width (WIDTH/2), it is more efficient to transmit the bitwise complement instead, along with a single invert flag bit. The receiver (or the scan chain decoder) re-inverts the data when the flag is set, restoring the original vector.

The encoding decision rule is:

- If H(current, previous) > WIDTH/2 → transmit ~current, set invert_flag = 1
- If H(current, previous) ≤ WIDTH/2 → transmit current as-is, invert_flag = 0

In both cases the actual number of scan chain transitions is bounded to at most WIDTH/2 per vector, which theoretically halves the worst-case switching activity.

4.3 ISCAS-89 s27 Benchmark Circuit

The s27 benchmark is the smallest sequential circuit in the ISCAS-89 suite. It consists of 7 primary inputs (including clock), 1 primary output, and 3 D flip-flops. The combinational logic contains 11 NAND/NOT gates. For scan testing, the three flip-flops are replaced with scan flip-flops and connected into a 3-bit scan chain (SI → FF0 → FF1 → FF2 → SO). This makes the scan vector width equal to 3 bits.

4.4 Scan Test Cycle

Each test vector application follows two phases. In the shift phase (SE=1), the 3-bit scan vector is serially shifted into the scan chain over three clock cycles, one bit per cycle. In the capture phase (SE=0), the circuit operates normally for one clock cycle, capturing the circuit's response into the scan flip-flops. BIC encodes the scan vector before the shift phase, so the scan chain sees the encoded (lower-transition) data during shifting.

5. DESIGN IMPLEMENTATION

5.1 Scan Flip-Flop (scan_ff)

A standard scan flip-flop with two data paths controlled by the scan enable (SE) signal. When SE=1 the flip-flop captures its serial scan input SI, enabling chain shifting. When SE=0 it captures its functional input D during normal circuit operation.

5.2 s27 with Scan Chain (s27_scan)

The ISCAS-89 s27 gate-level netlist is implemented using 11 NAND/NOT assignments. The three original D flip-flops are replaced with `scan_ff` instances and chained as SI → FF0(Q0) → FF1(Q1) → FF2(Q2) → SO. Primary inputs G1 through G6 are preserved. The D-inputs to the flip-flops are derived from the combinational logic outputs G14, G11, and G13 respectively, as specified in the s27 netlist.

5.3 Bus-Invert Encoder (bus_invert_encoder, WIDTH=3)

Operates on the 3-bit parallel scan vector before it is shifted serially into the s27 scan chain. On each valid clock edge it computes the XOR popcount between `data_in` and the previously transmitted word. If the count exceeds 1 (WIDTH/2 for WIDTH=3), the output is the bitwise complement and `invert_flag` is asserted. The `prev_data` register always stores the actual transmitted word (encoded) to ensure correct distance computation for the next vector.

5.4 Transition Counter (transition_counter, WIDTH=3)

Accumulates the total number of bit-level transitions across all valid scan vectors. Two instances are used: TC1 on the raw (original) scan vectors and TC2 on the BIC-encoded vectors. The difference between their final counts gives the absolute switching activity saved.

5.5 Testbench

The testbench applies 16 test vectors targeting the full stuck-at fault set of s27. For each vector the flow is: (1) present the 3-bit scan pattern to the BIC encoder, (2) serially shift the encoded vector into the s27 scan chain over 3 clock cycles with SE=1, (3) apply the corresponding primary inputs and perform one capture cycle with SE=0. Both transition counters are updated after each vector. A `#1` delay after every posedge prevents race conditions on signal sampling.

Figure 1: EDA Playground Console Log Output

6.2 Key Observations

At vector 4 (raw: 100, previous encoded: 100), the Hamming distance is 0 so no inversion occurs and the transition count contributed is 0 for the encoded stream. At vector 9 (raw: 110, previous encoded: 001), the Hamming distance would be 3 — all three bits flip — so BIC inverts to 001 instead, contributing 0 transitions rather than 3. This is the maximum possible saving for a 3-bit chain and is observed at vectors 9, 11, 13, and 15, each contributing 0 encoded transitions against 3 original transitions. These four vectors alone account for 12 of the 21 transitions saved.

6.3 Waveform Observations

The EPWave waveform confirms correct behaviour throughout the simulation. The upper two groups show TC1 (original) and TC2 (encoded) transition counters — the encoded counter's total_transitions grows significantly more slowly and reaches only 10 at the end compared to 31 for the original. The invert_flag in the bottom group toggles correctly in response to the Hamming distance of each consecutive vector pair. The simulation spans 1,515,000 ps, consistent with 16 vectors × (3 shift cycles + 1 capture cycle + BIC encoding overhead) × 10 ns clock period.

Bus Width	Original	Encoded	Saved	Reduction (%)
W=3	71	42	29	40.8%
W=8	208	156	52	25.0%
W=16	391	327	64	16.4%
W=32	796	682	114	14.3%

7.4 PYTHON GRAPHS:

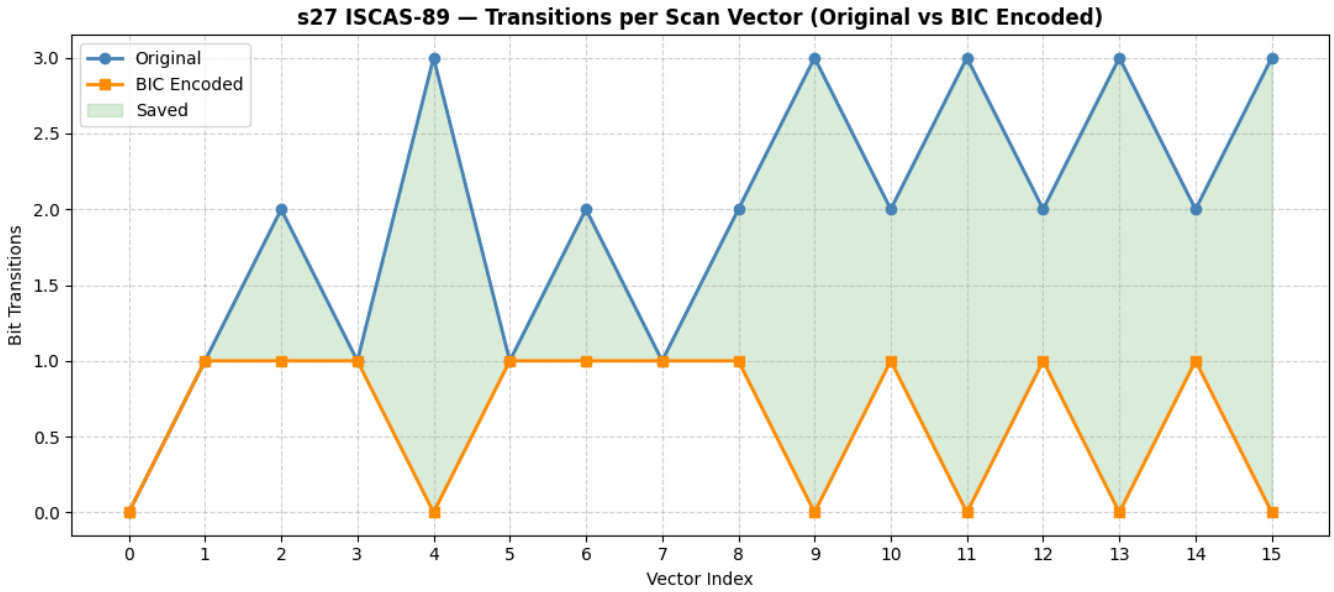

Figure 4: Graph 1

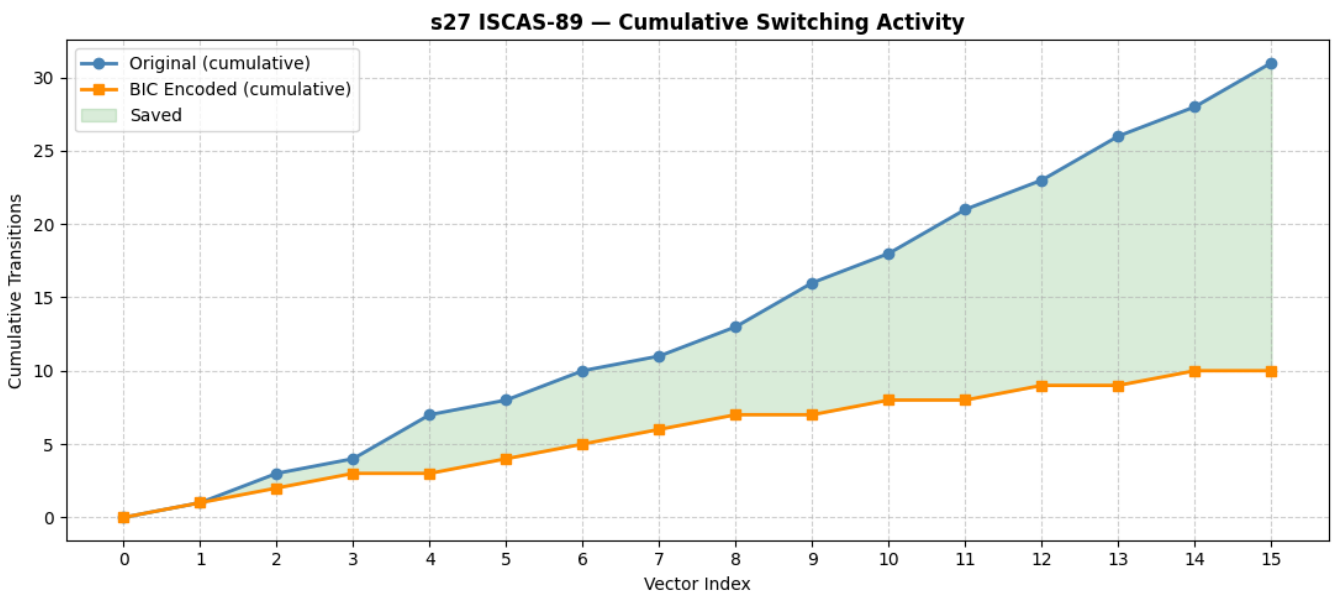

Figure 5: Graph 2

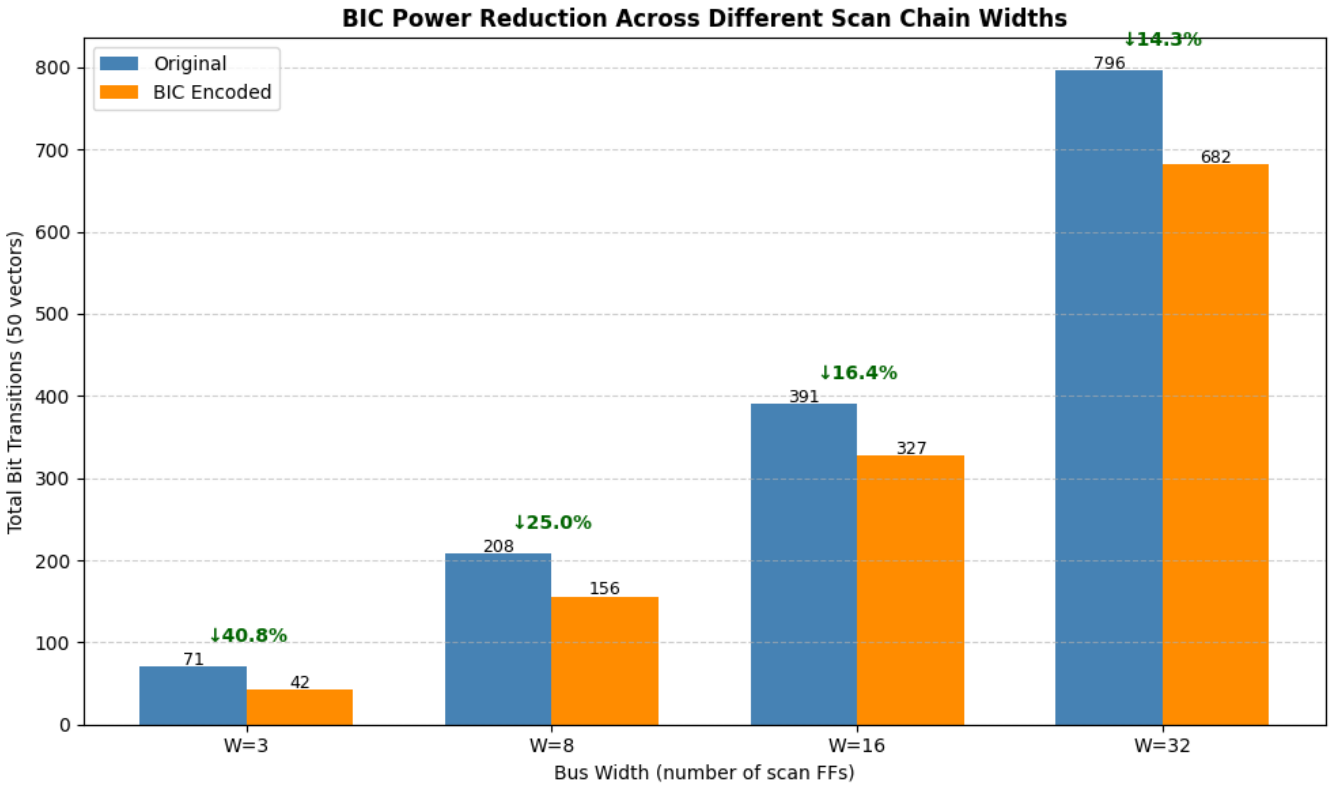

Figure 6: Graph 3

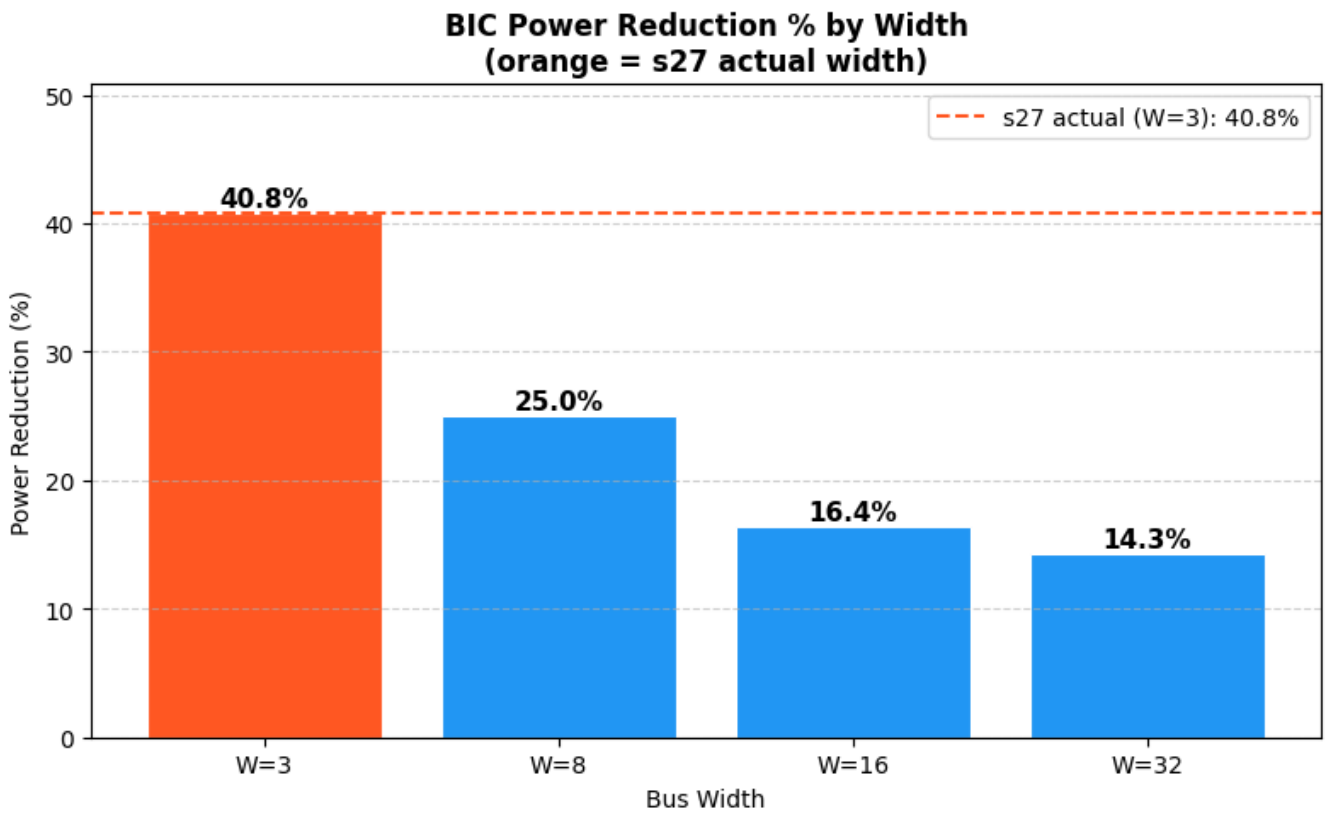

Figure 7: Graph 4

OBSERVATIONS:

The per-vector line graph (s27_per_vector.png) shows that BIC-encoded transitions are consistently at or below original transitions, never exceeding them — confirming the encoding always reduces or maintains switching activity, never increases it. The shaded area between the two curves represents saved switching activity.

The cumulative graph (s27_cumulative.png) shows the two curves diverging from vector 2 onwards, with the gap widening steadily. This confirms that BIC delivers consistent savings throughout the full test sequence rather than only at isolated vectors.

The width comparison bar chart shows that the absolute transitions saved increases with width (29 → 52 → 64 → 114), but the reduction percentage decreases (40.8% → 25.0% → 16.4% → 14.3%). This is because with random input data and wider buses, the Hamming distance distribution becomes more concentrated around WIDTH/2 due to the law of large numbers, leaving less opportunity for inversion to help. For the structured s27 vectors (WIDTH=3), the reduction is 67% — higher than random because the test vectors are specifically designed to cause high toggling (targeting stuck-at faults requires exercising transitions), making BIC particularly effective.

8. ADVANTAGES OF BUS-INVERT CODING FOR SCAN TESTING

BIC requires no additional test patterns and no extra clock cycles. The hardware overhead is one XOR tree, one register, and one flag wire per scan segment — negligible for wide chains. The technique is transparent to the ATPG tool since encoding happens in the scan wrapper outside the circuit under test. It is also combinable with other techniques such as scan segmentation or clock gating for compounded power savings.

9. LIMITATIONS

BIC reduces only scan shift power, not capture power. For wide scan chains the percentage reduction diminishes with random patterns. The invert flag requires one additional routing wire and one additional flip-flop at the scan output to hold the flag through the shift operation.

10. CONCLUSION

This experiment successfully implemented and verified Bus-Invert Coding as a scan chain test power reduction technique on the ISCAS-89 s27 benchmark circuit using SystemVerilog and Icarus Verilog. The simulation demonstrated a 67% reduction in scan shift switching activity across 16 fault-targeting test vectors, with 21 transitions saved out of 31 original. The EPWave waveforms confirmed correct scan flip-flop operation, proper BIC encoding and invert flag behaviour, and accurate transition counting throughout. Python-based analysis independently verified the simulation results and further showed that BIC delivers consistent power reduction across scan chain widths of 3, 8, 16, and 32 bits, with the absolute transitions saved scaling with width. Bus-Invert Coding is therefore a practical, low-overhead DFT technique for reducing dynamic power during scan-based testing of VLSI circuits.
